

Problem Set 2

Rosalie LaCroix

Due: February 18, 2026

Instructions

- Please show your work! You may lose points by simply writing in the answer. If the problem requires you to execute commands in **R**, please include the code you used to get your answers. Please also include the **.R** file that contains your code. If you are not sure if work needs to be shown for a particular problem, please ask.
- Your homework should be submitted electronically on GitHub in **.pdf** form.
- This problem set is due before 23:59 on Wednesday February 18, 2026. No late assignments will be accepted.

We're interested in what types of international environmental agreements or policies people support (Bechtel and Scheve 2013). So, we asked 8,500 individuals whether they support a given policy, and for each participant, we vary the (1) number of countries that participate in the international agreement and (2) sanctions for not following the agreement.

Load in the data labeled **climateSupport.RData** on GitHub, which contains an observational study of 8,500 observations.

- Response variable:
 - **choice**: 1 if the individual agreed with the policy; 0 if the individual did not support the policy
- Explanatory variables:
 - **countries**: Number of participating countries [20 of 192; 80 of 192; 160 of 192]
 - **sanctions**: Sanctions for missing emission reduction targets [None, 5%, 15%, and 20% of the monthly household costs given 2% GDP growth]

Please answer the following questions:

1. Remember, we are interested in predicting the likelihood of an individual supporting a policy based on the number of countries participating and the possible sanctions for non-compliance.

Fit an additive model. Provide the summary output, the global null hypothesis, and p -value. Please describe the results and provide a conclusion.

```
1 # Changing the variables to not be ordered factors and now just regular
  factors
2 climateSupport$countries <- factor(climateSupport$countries , ordered =
  FALSE)
3 climateSupport$sanctions <- factor(climateSupport$sanctions , ordered =
  FALSE)
4
5 # Run additive model
6 add_model2 <- glm(data = climateSupport ,
7                   choice ~ countries + sanctions ,
8                   family = binomial)
9
10 summary(add_model2)
```

The global null hypothesis states that neither of the variables, number of participating countries and sanctions for missing emission reduction targets, are significant in predicting whether or not an individual agrees with the given policy. The alternative hypothesis states that at least one of the variables listed is significant in predicting whether or not an individual agrees with the given policy.

$H_0: \beta_1 = \beta_2 = 0$, H_a : At least one $\beta \neq 0$

In Table 1, it can be seen that the coefficient for the number of participating countries, 0.458, is significant in predicting whether or not an individual agrees with a given policy. It can also be noted that the Table 1 indicates that the coefficients for the impact of sanctions also have significant linear predictive power in determining whether or not an individual agrees with a certain policy. At this point in analysis, it can be determined that the null hypothesis that all of these coefficients are equal to zero can be rejected, and that all of them bar the quadratic relationship for the number of participating countries, are significant in predicting the support of a policy and should be included in the regression model.

Table 1: Table of Coefficients

	<i>Dependent variable:</i>
	Choice Additive Model
Countries (80 of 192)	0.336*** (0.054)
Countries (160 of 192)	0.648*** (0.054)
Sanctions (5%)	0.192*** (0.062)
Sanctions (15%)	−0.133** (0.062)
Sanctions (20%)	−0.304*** (0.062)
Constant	−0.273*** (0.054)
Observations	8,500
Log Likelihood	−5,784.130
Akaike Inf. Crit.	11,580.260
<i>Note:</i> *p<0.1; **p<0.05; ***p<0.01	

2. If any of the explanatory variables are statistically significant in this model, then:

- (a) For the policy in which nearly all countries participate [160 of 192], how does increasing sanctions from 5% to 15% change the odds that an individual will support the policy? (Interpretation of a coefficient)

As an additive model has been fitted, the number of participating countries does not have an impact on the change in odds when increasing sanctions from 5% to 15%. The sanctions variable is in reference to the "None" level, so the difference between the coefficients for 5% and 15% sanctions must be mathematically compared against one another.

```
1 # 2a: Determining the log-odds difference between 5% and 15%
   sanctions.
2 coef(add_model2) ["sanctions15%"] - coef(add_model2) ["sanctions5%"]
```

```
sanctions15%
-0.3251028
```

This indicates that the in accordance with our additive model, holding all other variables constant, when the sanctions are increased from 5% to 15%, the log odds that an individual will support the policy decrease by 0.325.

- (b) For the policy in which very few countries participate [20 of 192], how does increasing sanctions from 5% to 15% change the odds that an individual will support the policy? (Interpretation of a coefficient)

As this is an additive model, the number of participating countries does not have an impact on the change in odds when increasing sanctions from 5% to 15%. To interpret the change in odds for increasing the sanctions, it will be the same at all levels of country participation and is therefore the same as in question 2(a). When sanctions are increased from 5% to 15%, and all other variables are held constant, the log odds that an individual will support the policy decrease by 0.325.

- (c) What is the estimated probability that an individual will support a policy if there are 80 of 192 countries participating with no sanctions?

The estimated probability that an individual will support a policy if there are 80 out of 192 countries participating with no sanctions can be determined by solving for the log odds and placing this into a formula to determine the probability that $y = 1$. The formula for this is as follows:

$$\pi_i = P(Y_i = 1|X_i) = \frac{\exp(\beta_0 + \beta_1 X_{1i} + \dots \beta_k X_{ki})}{1 + \exp(\beta_0 + \beta_1 X_{1i} + \dots \beta_k X_{ki})}$$

The coefficients for β_0 and β_1 can be input and utilized to solve for π_i , which is the probability that $Y_i = 1$ when β_1 represents the effect on the log odds that an individual will support a policy if there are 80 of 192 countries participating.

```
1 # 2c: Estimated probability an individual will support the policy if
  there are
2 # 80 out of 192 countries participating.
3 probability <- exp(coef(add_model2)["(Intercept)"] +
4                   coef(add_model2)["countries80 of 192"])/
5 (1 + exp(coef(add_model2)["(Intercept)"] +
6          coef(add_model2)["countries80 of 192"])
```

0.5159191

The estimated probability that an individual will support a policy if there are 80 of 192 countries participating with no sanctions is 0.5159, or 51.59%.

3. Would the answers to 2a and 2b potentially change if we included an interaction term in this model? Why?

Yes, the answers to 2a and 2b would potentially change if we included an interaction term in this model. This is due to the fact that we would no longer have an additive model and would now have an interaction model. An interaction model would mean that there is an interaction effect between the explanatory variables, such that a change in one variable impacts how the other variable affects the log-odds of the outcome variable. In this specific data, an interaction term would mean that the number of countries participating impacts the effect of how the sanctions for missing reduction targets affects the log-odds an individual supports a policy, or vice versa. For this reason, the answers to 2a and 2b would potentially change, as the change in odds that an individual supports the policy due to increasing sanctions from 5% to 15% could be different at differing levels of country participation due to the interaction between country participation and sanctions.

- Perform a test to see if including an interaction is appropriate.

```
1 # Run interaction model
2 int_model <- glm(data = climateSupport,
3                 choice ~ countries * sanctions,
4                 family = binomial)

1 # Perform test on additive vs interaction model
2 anova(add_model2, int_model, test = "LRT")
```

Analysis of Deviance Table

Model 1: choice ~ countries + sanctions

```

Model 2: choice ~ countries * sanctions
Resid. Df Resid. Dev Df Deviance Pr(>Chi)
